

$\kappa \equiv P_{\text{dyn}}/(fS) = CV^2$: campaign B, single GPU, all 108 SMs,
 one GEMM per curve, clocks locked at 15 MHz steps, P_{idle} measured at the
 same clock. The sweep originally ended at 1245 MHz because the largest shape hit the
 400 W board cap there -- a POWER limit, not a frequency one: the smallest shape holds
 1410 at 369 W while the others throttle from 1290 and 1305. (c) is why κ alone
 cannot say how far to downclock: total energy is $\kappa W + P_{\text{static}}T$ and the static
 term grows as f falls, so the measured total optimum (975-1020 MHz) sits ABOVE the
 point where κ stops improving (705-975 MHz).
